## ABSTRACT

**Objectives:** After a chronic intestinal injury, several intestinal cells switch their phenotype to activated myofibroblasts, which in turn release an abnormal amount of extracellular matrix proteins, leading to the onset of the fibrotic process. To date, no resolutive pharmacological treatments are available, and the identification of new therapeutic approaches represents a crucial goal to achieve. The onset, maintenance, and progression of inflammatory bowel disease are related to abnormal intestinal immune responses to environmental factors, including diet and intestinal microflora components. This study aimed to evaluate the potential antiinflammatory and antifibrotic effect of a biologically debittered olive cream and its probiotic oral administration in an experimental model of dextran sodium sulfate (DSS)–induced chronic colitis.

**Methods:** Chronic colitis was induced in mice by three cycles of oral administration of 2.5% DSS (5 d of DSS followed by 7 d of tap water). Mice were randomly divided into five groups: 10 control mice fed with standard diet (SD), 20 mice receiving SD and DSS (SD+DSS), 20 mice receiving an enriched diet (ED) with olive cream and DSS (ED+DSS), 20 mice receiving SD plus probiotics (PB; *Lactiplantibacillus plantarum* IMC513) and DSS (SD+PB+DSS), and 20 mice receiving ED plus PB and DSS (ED+ PB+DSS). Clinical features and large bowel macroscopic, histologic, and immunohistochemical findings were evaluated.

**Results:** The simultaneous administration of ED and PB induced a significant reduction in macroscopic and microscopic colitis scores compared with the other DSS-treated groups. In addition, ED and PB led to a significant decrease in the expression of inflammatory cytokines and profibrotic molecules.

**Conclusions:** The concomitant oral administration of a diet enriched with biologically debittered olive cream and a specific probiotic strain (*Lactiplantibacillus plantarum* IMC513) can exert synergistic antiinflammatory and antifibrotic action in DSS-induced chronic colitis. Further studies are needed to define the cellular and molecular mechanisms modulated by olive cream compounds and by *Lactiplantibacillus plantarum* IMC513.

## Introduction

Crohn's disease and ulcerative colitis are the two major inflammatory bowel diseases (IBDs). These chronic relapsing disorders cause critical alterations to intestinal functions owing to the development of fibrosis. Intestinal fibrosis can cause severe complications such as stenosis and obstructions [1–3]. Intestinal fibrosis is the result of an abnormal and uncontrolled deposition of extracellular matrix (ECM) proteins. The excessive accumulation of ECM proteins is owed to their increased production by locally activated myofibroblasts or to their reduced degradation by metalloproteinases. In intestinal fibrogenesis related to chronic inflammation, different cell types, including fibroblasts, subepithelial myofibroblasts, smooth muscle cells, epithelial cells, and endothelial cells, as well as pericytes and staminal cells, undergo differentiation processes and become activated ECM-producing myofibroblasts [4–6].

In most organs, including the intestine, one of the key players of inflammation and fibrosis is transforming growth factor  $\beta 1$  (TGF- $\beta 1$ ). This cytokine can act not only through its canonical interaction with small mothers against decapentaplegic proteins (SMADs) but also with several other transduction pathways such as mammalian target of rapamycin and mitogen-activated protein kinase. Transforming growth factor  $\beta 1$  interacts with numerous proinflammatory and antiinflammatory signaling pathways as well as profibrotic and antifibrotic molecules [7–13].

Current IBD therapies include the administration of 5-aminosalicylic acid, steroids, antibiotics, probiotics, and immunosuppressive or biological drugs (anti-tumor necrosis factor [TNF], anti-interleukin [IL]-6, anti-IL-17, anti-IL-12, anti-IL-23, anti- $\alpha 4\beta 7$ , and anti-integrin monoclonal antibodies) [14–17]. All these drugs are effective in improving both acute and chronic inflammation, but they fail to prevent or reverse intestinal fibrosis. Bowel surgery remains the only available treatment for intestinal fibrostenosis. Therefore, the identification of new preventive strategies appears to be a necessary approach to avoid IBD-related intestinal fibrosis.

It is well known that several plants and algae extracts (i.e., artemisinin and spirulin) act as nutraceuticals, exerting beneficial effects on different diseases [18–23]. Natural drugs and dietary components may strongly modulate the gut immune response and microbiome [24–28]. In turn, the gut microbiome is known to interact with and affect distant systems and their functions, such as the central nervous system [29].

Furthermore, the microbiome can also be directly modulated by a dietary regimen. The Mediterranean diet appears to be a promising nutritional regimen in the prevention and management of several inflammatory disorders, including IBD. It is composed of a mix of fruit and vegetables (rich in fiber, vitamins, and antioxidants), grains and nuts, and virgin olive oil (containing monounsaturated and polyunsaturated fatty acids and phenolic compounds) [24,27,30–32]. In particular, *in vitro* and *in vivo* studies have highlighted the ability of polyphenols from olive oil to mitigate clinical and histological features of experimentally induced colitis [33–36].

Phenolic molecules suppress the expression of proinflammatory molecules, inhibit the activity of oxidant enzymes, and regulate several inflammatory signaling pathways [33–36]. Furthermore, some reports have shown that the oral administration of probiotics (i.e., lactic acid bacteria [LAB] and *Bifidobacterium* species) may contribute to the recovery of microbiome compositions and the maintenance of intestinal mucosa integrity [27,31,37,38]. Among the LAB, many strains of *Lactiplantibacillus* (*Lpb.*) *plantarum*, such as Sanriku-SU7, LP01, 03 06, and CBT LP3,

have been shown to exert beneficial effects on animal models of colitis, including in patients with IBD [39–44], leading to an increasing scientific interest in selecting specific probiotic strains that are effective in the treatment of IBD [45,46]. The mechanisms behind the beneficial effects of probiotics remain to be elucidated.

During the mechanical extraction of virgin olive oil, more than 47% of the total phenols present remain in the pomace [47]. The destoned pomace may represent an important food source of phenolic compounds, mainly derivatives of secoiridoids, but its gustatory acceptability may be achieved (as in the case of table olives) after a debittering process that is able to chemically or biologically hydrolyze the bitter secoiridoids into their aglycon phenolic derivatives. This processed product is a new kind of “olive cream.”

We hypothesize that the administration of a natural phenolic source in association with probiotics could mitigate colitis. In particular, the antigenotoxic and immunomodulatory effects of these compounds could be related to the activation of TGF- $\beta$ –SMADs and TGF- $\beta$ –non-SMADs signaling. Therefore, this study aimed to evaluate the potential antiinflammatory and antifibrotic role of administering biologically debittered olive cream produced from destoned pomace and a specific probiotic (*Lpb. plantarum* strain) in dextran sodium sulfate (DSS)–induced chronic colitis.

## Materials and methods

This study was conducted according to the guidelines of the Declaration of Helsinki and the National Institutes of Health Guide for the Care and Use of Laboratory Animals (publication number 85-23, 1985) and was approved by the Institutional Review Board of the Ministero della Salute (authorization number 869/2018-PR Prot. CE5C5.20).

### Olive cream

Destoned pomaces for olive cream production were obtained from olives (cv. Moraiolo) and processed by means of an industrial three-phase Alfa Laval decanter (0.3 ton/h) equipped with an olive destoner machine (AlfaOliver 500). Pomaces were subjected to the debittering process and analyzed for their phenolic composition by high-performance liquid chromatography with diode-array detection after phenol extraction. The analysis method has been described by Tuffariello et al. [48].

### Bacterial strains and debittering process

All strains used in this study belong to the collection of the Faculty of Bioscience and Technology for Food, Agriculture, and Environment of the University of Teramo. In particular, two *Lpb. pentosus* strains, previously characterized for their oleuropeinolytic activity, were used as starter culture mixtures to produce olive cream through the biological debittering of the olive destoned pomace. Briefly, before olive pomace inoculation, *Lpb. pentosus* strains (used as debittering starter mixtures) were subcultured overnight in de Man, Rogosa, and Sharpe broth (Oxoid Ltd., Basingstoke, United Kingdom) at 30°C. Subsequently, bacterial cells were centrifuged, washed, and resuspended in sterile saline solution (0.85% weight/volume).

Destoned olive pomace was unfrozen overnight at room temperature and aliquoted (800 g) into sterilized glass vessels. Subsequently, after the addition of glucose (20g/L) and yeast extract powder (10 g/L), the olive pomace was thermally stabilized in an autoclave at 121°C for 5 min. The olive pomace was inoculated with a mixture (1:1 ratio) of the two *Lpb. pentosus* strains at a final concentration of 10<sup>7</sup> colony forming units (CFU)/mL and incubated at 30°C for 72 h to allow fermentation to occur. The fermentative activity of the starter mixture was confirmed by monitoring microbial communities, pH, and titratable acidity as well as the evolution of the phenolic composition (data not shown).

In addition, the human-derived probiotic *Lpb. plantarum* IMC513 (Synbiotec S. r.l., Camerino, Italy), which previously has been characterized to possess several beneficial properties including antiinflammatory effects in *in vitro* intestinal cell models [49–53], was used as a dietary adjunct in tap water at a final concentration of 10<sup>9</sup> CFU/mL/mice/die. The dosage was selected based on similar experiments reported in the current literature [54,55].

### Animals

The induction of experimental colitis was carried out at the Department of Biotechnological and Applied Clinical Sciences, University of L'Aquila (L'Aquila, Italy). All experiments complied with government guidelines (European Economic

Community Council Directive 86/609, OJ 358, December 1, 1987; Italian Legislative Decree 116/92, Gazzetta Ufficiale della Repubblica Italiana no. 40, February 18, 1992; National Institutes of Health Guide for the Care and Use of Laboratory Animals, publication no. 85-23, 1985) and approved by the Minister of Health (authorization number 869/2018-PR Prot. CE5C5.20).

Ninety C57BL/6 wild-type male mice were included in the study (Charles River Laboratories, Lyon, France). All animals were housed in a plastic cage and kept in a pathogen-free environment at constant room temperature, with a 12 h/12 h light/dark cycle and food and water ad libitum.

We provided animals with 20 g dry weight of food at 100 g/animal/d, according to Animal Research Review Panel guidelines. The animals were housed two or three per cage to guarantee social behavior and equal access to food. At 20 d of life, the mice were randomly divided into five groups: 10 mice received a standard diet (SD) and were used as controls; 20 received SD and DSS (SD+DSS); 20 received an enriched diet (ED) with 10% biologically debittered olive cream and DSS (ED+DSS); 20 received SD plus probiotic (PB; *Lpb. plantarum* IMC513) and DSS (SD+PB+DSS); and 20 received ED plus PB and DSS (ED+PB+DSS).

#### Experimental procedures

Chronic colitis was induced in mice by oral administration of 2.5% w/v DSS (molecular weight: 36 000–44 000 kDa, purchased from TdB Labs, Uppsala, Sweden). The DSS was solubilized in autoclaved tap water and administered ad libitum for three cycles (5 d of DSS followed by 7 d of tap water). The control group received only tap water.

Two groups of animals (ED+DSS and ED+PB+DSS) received DSS in tap water and were fed with chow enriched with 10% biologically debittered, core-free olive cream. The phenolic composition of the fermented cream used in the enriched diet is reported in Table 1. Both SD and ED chow were produced by Mucedola S.r.l. (Milan, Italy).

Two groups of animals (SD+PB+DSS and ED+PB+DSS) received DSS and the *Lpb. plantarum* IMC513 probiotic strain in tap water as follows: 10<sup>9</sup> CFU/mL/mouse/d, equivalent to 10 mg in 10 mL of tap water/mouse/die.

#### Sample recovery, preparation, and assessment of colonic injury

Animals were monitored daily for fluid intake and weight changes and examined for signs of colitis, including weight loss and diarrhea (scored on a 0–2 scale as follows: 0 = absence, 1 = mild, and 2 = severe) [56].

Body weight was measured every week. Four days after the last DSS cycle, all animals were euthanized by carbon dioxide. Following laparotomy, the colon was identified, rapidly excised, and photographed. On a scale from 0 to 2, the presence of adhesions between the colon and adjacent organs was assessed. The length and the weight of the colon were measured and the colon was then scored for macroscopic lesions. Then, colonic tissue samples were fixed in 4% buffered formaldehyde and embedded in paraffin for histological and immunohistochemical analysis.

#### Macroscopic and microscopic evaluation of colonic injury

Colon length and weight were measured to score the macroscopic lesions by two independent observers on a 0–2 scale as follows: colonic adhesions (0 = absence, 1 = mild or focal zonal, 2 = severe or diffuse); colonic dilation (0 = absence, 1 = mild, 2 = severe); and colonic thickness (0 = normal, 1 = mild

increase, 2 = marked increase [ $>3$  mm]) [56]. The total macroscopic score was expressed as the sum of the individual scores of colonic alterations.

To evaluate microscopic features, colonic samples were subjected to conventional histological procedures: they were fixed in 4% buffered formalin in phosphate buffer saline (PBS) at pH 7.4 for 3 h at room temperature and then paraffin embedded. Serial 3- $\mu$ m sections were stained with hematoxylin and eosin to assess organ morphology and highlight the degree of inflammation and with Masson's trichrome stain to detect connective tissue deposition and evaluate the stage of fibrosis. The stained sections were observed under an Olympus BX51 Light Microscope (Olympus Optical Co. Ltd, Tokyo, Japan) and scored in a double-blind manner according to the presence of ulcerations (0 = absent, 1 = small ulcers, 2 = big ulcers), degree of inflammation (0 = absent, 1 = mild, 2 = moderate, and 3 = severe), depth of the lesions (0 = absent, 1 = lesions extending into the submucosa, 2 = lesions in the muscularis propria, and 3 = lesions in the serosa), and degree of fibrosis (0 = absent, 1 = mild, 2 = moderate, 3 = severe) [49]. The total microscopic score was expressed as the sum of the individual scores.

Signs of intestinal inflammation were scored as absent, mild, moderate, or severe according to the density and the extent of the inflammatory infiltrate, the loss of goblet cells, and the thickening of the bowel wall.

Fibrosis staging was assessed by Masson's trichrome staining as mild, moderate, or severe based on the density and the extent of the connective tissue as well as the disruption of tissue architecture.

#### Immunohistochemistry analyses

Colonic specimens were fixed in 4% buffered formalin in PBS (pH 7.4) for 3 h, dehydrated in graded ethanol, and embedded in low-melting paraffin. Sections (3  $\mu$ m thick) were incubated in methanol for 40 min and then in 3% hydrogen peroxide for 5 min. Samples were incubated overnight at 4°C with specific antibodies (Table 2). To control for the specificity of the immune reactions, control sections were incubated omitting the primary antibody.

The specimens were washed in PBS (three times for 5 min each) and incubated with streptavidin-biotin-peroxidase-conjugated secondary antibody (K0675; DakoCytomation, Milano, Italy). After being rinsed in PBS for 10 min, the sections were incubated with 3,3'-diaminobenzidine-tetrahydrochloride for 1–3 min. Finally, the sections were counterstained with Mayer's hematoxylin, mounted, and observed under an Olympus BX51 Light Microscope.

#### Semiquantitative digital image analysis of immunohistochemical staining

Semiquantitative comparison of immunohistochemical staining was measured using ImageJ, public domain software for digital image analysis [57]. The immunohistochemistry profiler software plugin was required. Immunopositivity was expressed as a percentage of the total software-classified areas, and the data obtained were plotted as histograms. Results were expressed as means  $\pm$  standard deviation; a *P* value  $<0.05$  was considered statistically significant.

#### Statistical analysis

Histological scores were reported as means  $\pm$  standard error of the means. Analysis of variance with the post hoc Mann–Whitney *U* test was used to determine differences between groups for normally and not normally distributed data, respectively, at *P*  $<0.05$ . Analyses were conducted using GraphPad Prism, version 7.00 (GraphPad Software, Inc., La Jolla, California, United States).

## Results

Biologically debittered olive cream and probiotic oral administration improved DSS-induced chronic colitis and fibrosis.

#### Effect of the administration of biologically debittered olive cream and probiotics on clinical features and macroscopic and microscopic findings

First, the effects of treatments on the health and zoometric parameters were assessed. Male C57BL/6J mice were monitored for body weight at 1, 2, 3, and 4 wk, and no significant loss of body weight was observed in any group (Fig. 1A). Dextran sodium sulfate acts as chemical irritant in the large intestine, inducing inflammation and alteration in the organ structure. Macroscopic evaluation revealed a significant increase in colon weight (referred to as the last 8 cm of the distal large bowel) and a reduction in colon length in SD+DSS mice compared with the control group (Fig. 1B, C; Table 3).

**Fig. 1.** (A) Body weights. Mice were weighed at 1, 2, 3, and 4 wk. No significant differences were found among the groups. (B) Macroscopic evaluation of explanted colons at 36 d posttreatment. Representative images of the macroscopic appearance of the colon from mice in the five different groups (SD, SD+DSS, ED+DSS, SD+PB+DSS, and ED+PB+DSS). (C) Assessment of colon length. Values are means  $\pm$  standard errors of means. Statistical significance was calculated via analysis of variance ( $P < 0.05$ ). DSS, dextran sodium sulfate; ED, enriched diet; PB, probiotic; SD, standard diet.

The main macroscopic signs associated with chronic DSS administration (dilatation, thickness, stenosis, and adhesions) were improved in mice that were simultaneously fed with olive cream-enriched chow and probiotics. The total macroscopic score was lower in mice treated with ED+PB+DSS versus those treated with SD+DSS (Table 3; Fig. 2).

The other DSS-treated groups did not show significant improvement in colonic parameters associated with DSS administration or a reduction in total macroscopic score compared with SD+DSS mice (Table 3; Fig. 2). After the second cycle of oral administration of DSS, evident signs of disease, including reduced mobility, a decrease of social interactions, raised fur, and diarrhea, were detected in all DSS-treated mice.

Chronic administration of DSS can induce both colorectal inflammation and fibrosis. Histomorphology evaluation, as assessed by hematoxylin and eosin staining, showed marked signs of inflammation in SD+DSS mice compared with SD mice

and ED+PB+DSS mice (Fig. 3A). Inflammation involved the mucosal and submucosal layers and was characterized by increased infiltration of inflammatory cells and a decrease in goblet cells as well as reduction and alteration of crypt architecture. Features of inflammation were also found in ED+DSS and ED+PB+DSS mice, although to lesser degree compared with SD+DSS mice (Fig. 3A). Masson's trichrome staining highlighted signs of fibrosis in SD+DSS mice compared with the other groups (Fig. 3B). In particular, an increase in collagen deposition was observed in the mucosa, submucosa, and serosa layer of SD+DSS mice, which decreased in the other DSS-treated groups (mainly in ED+PB+DSS mice) (Fig. 3B). The total microscopic score showed a significant reduction in inflammation and signs of fibrosis in the ED+PB+DSS group compared with SD+DSS-treated mice (Fig. 3C, D). No noticeable improvement in these parameters was observed in mice receiving ED+DSS or SD+PB+DSS (Fig. 3C, D).

**Fig. 2.** Total macroscopic score evaluation. The total macroscopic score was calculated as the sum of the score of individual macroscopic lesions (dilatation, thickness, stenosis, and adhesions). Mice receiving ED+PB+DSS showed a significant reduction in macroscopic score compared with the group receiving SD+DSS. DSS, dextran sodium sulfate; ED, enriched diet; PB, probiotic; SD, standard diet.

#### Effect of fermented olive cream and probiotic oral administration on the expression of inflammatory and fibrotic cytokines

Generally, macroscopic and structural changes of the intestine owing to inflammation and fibrogenesis are associated with an abnormal cytokine profile. To assess the degree of inflammation, we performed immunohistochemical analysis, examining the inflammatory cytokines IL-1 $\beta$ , IL-6, and TNF- $\alpha$  (Fig. 4A–C). As expected, all three markers were increased in SD+DSS mice compared with the controls. Furthermore, a noticeable reduction was detected in ED+PB+DSS mice compared with the other groups, as confirmed by semiquantitative analysis of each of the examined cytokines (Fig. 4D–F).

Chronic inflammation leads to extracellular matrix deposition and contributes to the onset and progression of fibrosis. To evaluate the fibrogenesis status in our experimental groups, we assessed the expression of TGF- $\beta$ 1, the pivotal driver of intestinal fibrosis. Although TGF- $\beta$ 1 was expressed in all DSS-treated mice (Fig. 5A), a significant increase in this protein was detectable in SD+DSS mice compared with the ED+PB+DSS group, confirming the ability of olive phenols and probiotics to reduce the progression of fibrosis (Fig. 5A, C).

The TGF- $\beta$ 1 profibrotic signal acts through the activation of the downstream SMADs cascade. Accordingly, we found a significant overexpression of p-SMAD3 in SD+DSS mice as well in the other DSS-treated mice compared with the ED+PB+DSS group (Fig. 5B,

D). These data for both TGF- $\beta$ 1 and p-SMAD3 were supported by the semiquantitative analyses results (Fig. 5C, D).

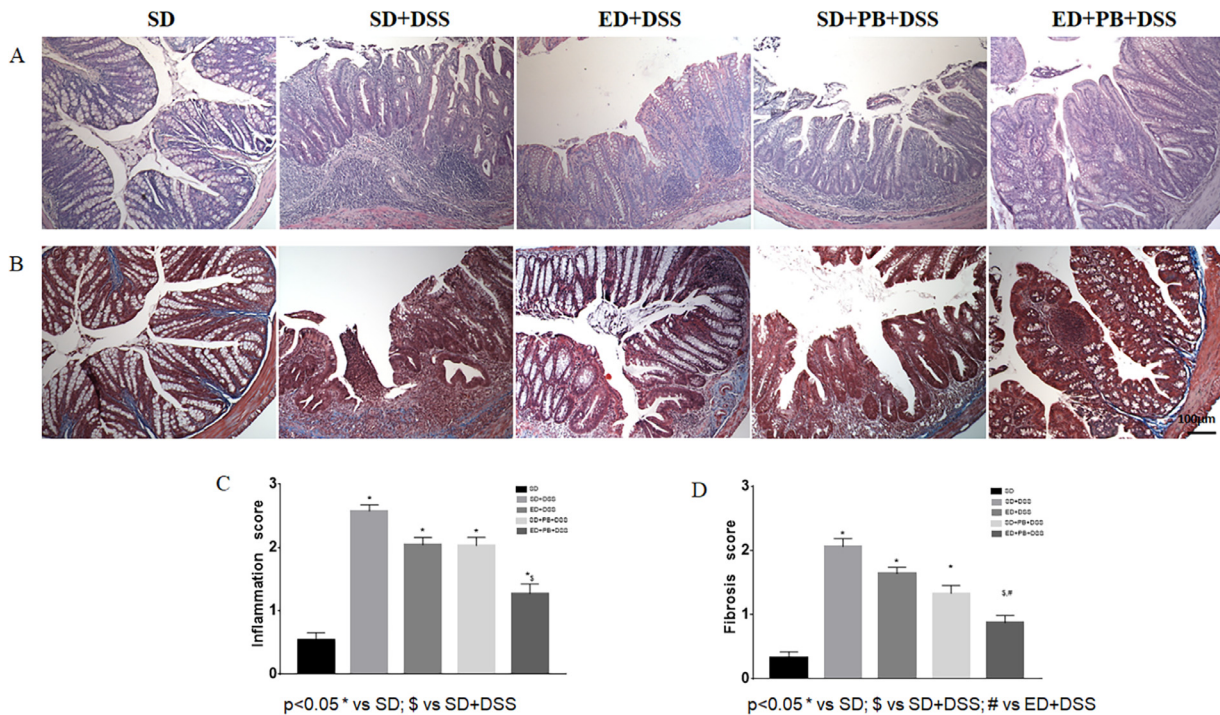

To analyze the ability of TGF- $\beta$ 1 to regulate fibrosis through its noncanonical pathway, we assessed the expression of phosphatidylinositol 3-kinase (PI3K) and phosphorylated protein kinase (p-Akt) (Fig. 6). These molecules are strongly associated with the release of inflammatory cytokines and the fibrotic process.

Expression of PI3K was significantly increased in SD+DSS mice compared not only with the SD group but also with ED+DSS+PB mice, confirming an improvement in fibrosis attributable to the simultaneous administration of olive cream and probiotics (Fig. 6A).

Similarly, immunohistochemistry staining for p-Akt showed a noticeable reduction in ED+PB+DSS mice, comparable with SD mice, with respect to the other experimental groups (Fig. 6B). These results were validated by semiquantitative analyses (Fig. 6C, D).

To investigate the beneficial effects of the administration of fermented olive cream and *Lpb. plantarum* on DSS-induced colitis, we assessed the fibrotic markers alpha smooth muscle actin ( $\alpha$ -SMA) and collagens I–III (Fig. 7).

Immunohistochemistry analysis highlighted the increased expression of  $\alpha$ -SMA in SD+DSS mice compared with the other groups (Fig. 7A). In particular, in SD+DSS-treated animals,  $\alpha$ -SMA immunopositivity was present not only in the muscle cells of the muscularis mucosa and muscularis propria but in the lamina

**Fig. 3.** (A) Hematoxylin and eosin staining. (B) Masson's trichrome staining. Original magnification: 10 ×; scale bar: 100 μm. Mice receiving ED+PB+DSS showed a significant reduction in signs of chronic inflammation and fibrosis compared with the other DSS-treated groups. (C) Inflammation score. (D) Fibrosis score. Graphs of inflammation (calculated as 0 = absent, 1 = mild, 2 = moderate, and 3 = severe) and fibrosis (calculated as 0 = absent, 1 = mild, 2 = moderate, and 3 = severe) scores showed a significant reduction in colitis features in ED+PB+DSS mice compared with mice in other groups. DSS, dextran sodium sulfate; ED, enriched diet; PB, probiotic; SD, standard diet.

propria, submucosa, and serosa layers. In ED+PB+DSS mice, expression was mostly restricted to the typical layers, which was also observed for SD-fed mice (Fig. 7A). Evaluation of collagens I–III revealed poor immunopositivity in ED+PB+DSS the group, which was similar to the control. Conversely, the expression of collagens I–III was significantly increased in the other DSS-treated mice (Fig. 7B). These results, for both  $\alpha$ -SMA and collagens I–III, were confirmed by semiquantitative evaluation (Fig. 7C, D).

## Discussion

Chronic intestinal inflammation commonly leads to fibrosis, owing to the uncontrolled production and deposition of ECM components. This process is modulated by both profibrotic and antifibrotic factors [9]. Intestinal fibrosis plays a central role in the changes that occur to the intestinal wall architecture, which can lead to strictures, obstruction, and loss of function. The pathophysiology of intestinal fibrosis is still unclear, although several risk factors including diet, environmental factors, immune response, pathogens, genetic alterations, and the intestinal microbiome contribute to its onset and progression [58–62]. The gut microbiome ecosystem is essential for the maintenance of intestinal barrier functions, and its disruption seems to play a pivotal role in the development of chronic intestinal inflammation and fibrosis, which occurs in IBD.

Various animal models have provided significant and relevant insights toward understanding the histopathological and morphological changes that occur in the intestinal wall. Colitis induced by DSS, one of the most frequently used models of experimental colitis, causes intestinal epithelial barrier disruption with a consequent massive passage of intraluminal microbes and antigens into the mucosa and submucosa,

triggering the local inflammatory response [63]. Dextran sodium sulfate induces mucin depletion, altering the mucus layers adhering to the mucosal surface, making it more permeable to luminal microbes. Colitis induced by DSS is associated with significant intestinal dysbiosis [63,64].

Dietary habits have been strongly linked to the maintenance of intestinal epithelium homeostasis. Alterations of this homeostasis contribute to the pathogenesis of chronic intestinal inflammation and the related risk of colorectal cancer. In recent years, great attention has been focused on the correlation between the Western diet, characterized by a high amount of fat and low amounts of fruits and vegetables, and the alarming increase in the incidence of several disorders, including IBD and colorectal cancer [58–61,65,66]. On the contrary, the Mediterranean diet, which is rich in fruits, vegetables, grains, nuts, and olive oil, represents one of the most promising dietary regimens for the prevention and management of intestinal disorders [67].

In particular, the beneficial effects on health of extra virgin olive oil, attributed to the monounsaturated fat content and to the presence of phenolic compounds, include antioxidant, anti-inflammatory, and immunomodulatory properties. Among dietary components, monounsaturated fatty acids and phenolic compounds appear to be beneficial for gut health [68,69].

Consumption of extra virgin olive oil causes a strong anti-inflammatory effect on the gut mucosa, because it interacts with antioxidant molecules (i.e., hydroxytyrosol, squalene, and oleuropein derivatives) to modulate intestinal permeability and modify the intestinal microbiota [70,71].

Moreover, increasing attention has been paid to the development of nondairy fermented foods such as vegetable food matrices to overcome the limitations of lactose intolerance and vegetarian or cholesterol-restricted diets. Among the products of vegetable

**Fig. 4.** (A–C) Immunohistochemistry of the inflammatory cytokines IL-6, IL-1 $\beta$ , and TNF- $\alpha$ . Original magnification: 10  $\times$ ; scale bar: 100  $\mu$ m. The expression of the indicated inflammatory molecules was decreased in ED+PB+DSS mice compared with the other DSS-treated groups. (D–F) Semiquantitative evaluation of IL-6, IL-1 $\beta$ , and TNF- $\alpha$ . This analysis confirmed a significant reduction in the examined inflammatory cytokines in the ED+PB+DSS group.  $P < 0.05$  versus SD (\*) and SD+DSS (s). origin, table olives and their derivatives (i.e., olive cream) represent an important source of fiber and bioactive molecules such as phenolic compounds and triterpene acids. The palatability of olive cream (as for table olives) is achieved after a fermentation process that is able to hydrolyze bitter secoiridoids and enhance the sensory and aromatic profile of the final product. Biotransformation using selected LAB is a suitable alternative to chemical hydrolysis [72]. Several studies have shown that olive hydrophilic phenols (mainly secoiridoids, exclusive to the *Oleaceae* family) exert antioxidant, antimicrobial, and antiinflammatory activities, leading to numerous health benefits such as a reduction in cardiovascular risk factors and the prevention of various chronic diseases, chronic inflammation, stroke, and other degenerative diseases [48,73–76].

Accordingly, several studies have shown the ability of some probiotics to reduce intestinal inflammation in experimental models of colitis [76–78]. Among probiotics, *Lpb. plantarum* represents one of the most versatile and promising species for its various health-promoting effects; thus, the administration of *Lpb. plantarum* strains has shown a promising role in ameliorating colon

inflammation in different models of experimental colitis [43,79–83]. The promising use of *Lpb. plantarum* probiotic strains as a dietary intervention to prevent and/or attenuate gut inflammatory diseases such as IBD was also recently confirmed in human intervention studies [84–86].

In general, probiotics attenuate colon inflammation by downregulating inflammatory signaling as well as modulating mucosal immunity and gut microbiota [43]. The mechanisms behind these beneficial effects are still unclear; however, *Lpb. plantarum* has been found to be able to prevent and/or ameliorate IBD conditions, mainly by modulating specific proinflammatory and antiinflammatory pathways [87].

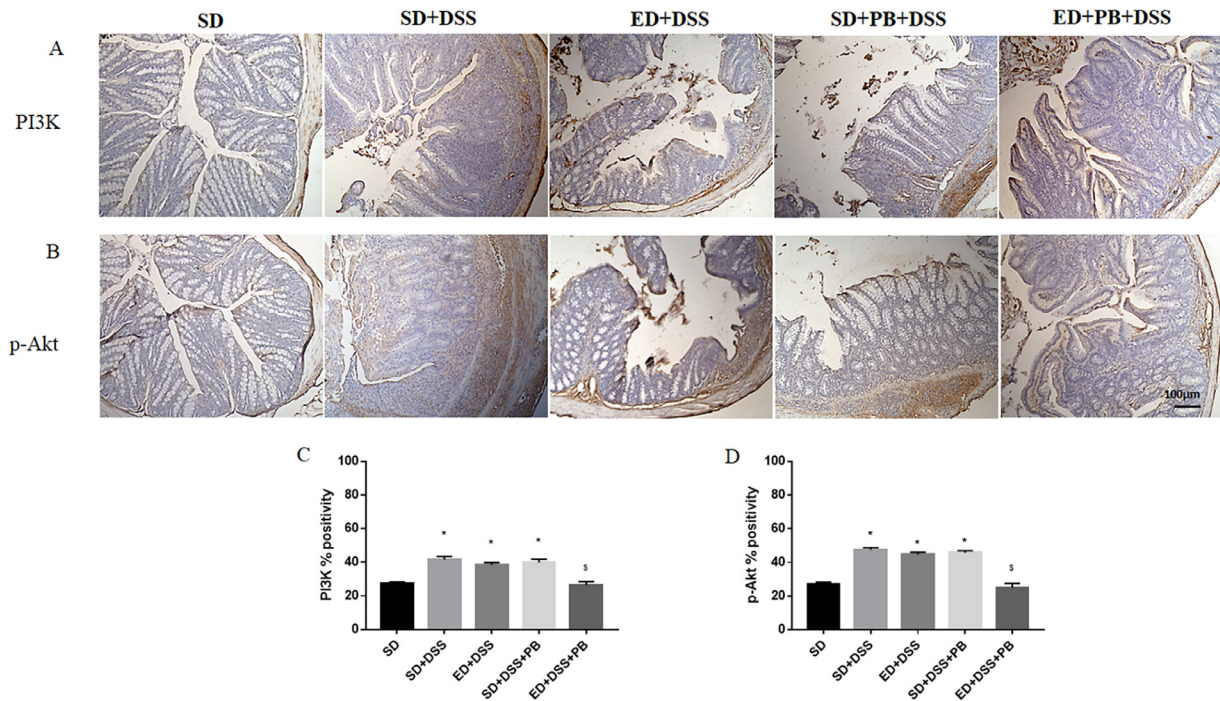

In particular, the production of proinflammatory cytokines such as TNF- $\alpha$ , IL-1 $\beta$ , and IL-6 in Bagg Albino/c in DSS-induced colitis in mice was reduced by the oral administration of *Lpb. plantarum* K68 [88]. A similar antiinflammatory effect was found following the administration of *Lactobacillus brevis* K65 [89]. The beneficial effect of *Lpb. plantarum* 06CC2 in DSS-induced colitis in mice was found to be mainly owed to the increased production of the antiinflammatory cytokine IL-10 [82].

**Fig. 5.** (A, B) Immunohistochemistry of TGF- $\beta$ 1 and p-SMAD3 molecules. Original magnification: 10  $\times$ ; scale bar: 100  $\mu$ m. An increased expression of both TGF- $\beta$ 1 and p-SMAD3 was seen in DSS-treated mice compared with the ED+PB+DSS group. (C, D) Semi-quantitative evaluation of TGF- $\beta$ 1 and p-SMAD3. This analysis validated the significant increase in the expression of these molecules in SD+DSS mice compared with the ED+PB+DSS group.  $P < 0.05$  versus SD (\*) and SD+DSS (<sup>§</sup>). DSS, dextran sodium sulfates; ED, enriched diet; PB, probiotic; SD, standard diet; SMAD, small mothers against decapentaplegic protein; TGF, transforming growth factor.

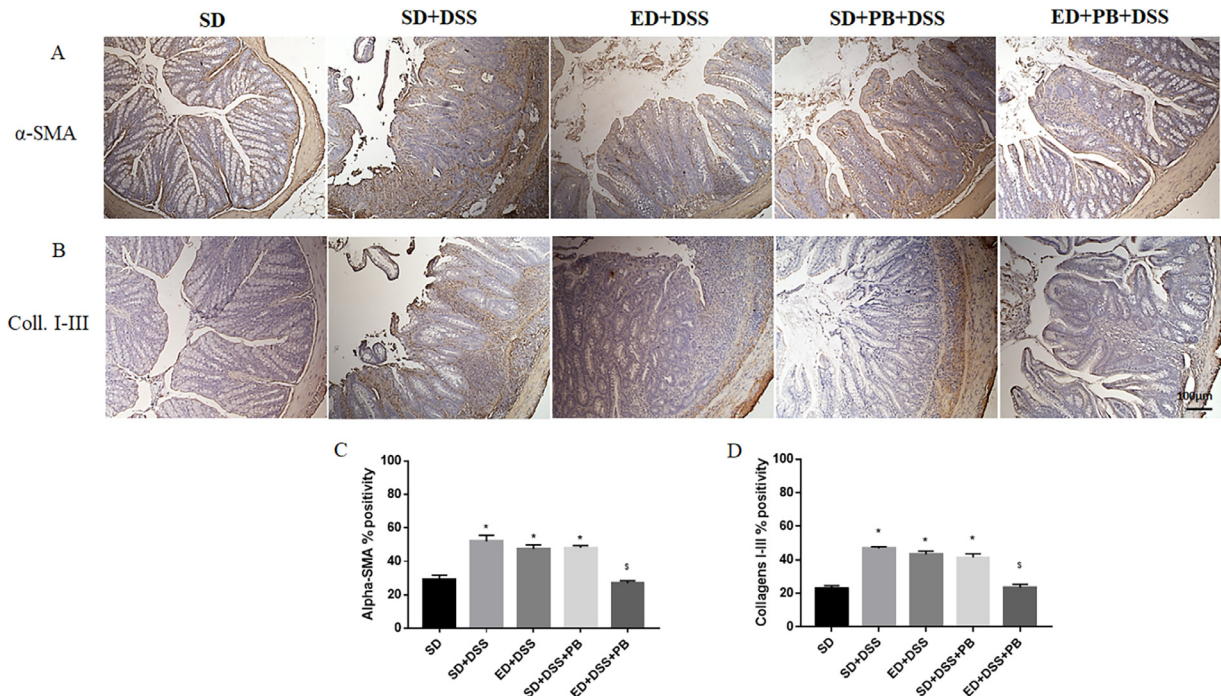

This study showed that the simultaneous oral administration of a diet enriched with fermented olive cream and a probiotic significantly improved both intestinal inflammation and

fibrosis in the experimental model of DSS-induced colitis. The mice receiving ED+PB+DSS showed a reduction in the clinical features and the macroscopic and microscopic parameters of

**Fig. 6.** (A, B) Immunohistochemistry of PI3K and p-Akt. Original magnification: 10  $\times$ ; scale bar: 100  $\mu$ m. A significant increase in PI3K and Akt expression was seen in DSS-treated groups compared with ED+PB+DSS mice, in which the positivity was similar to control mice. (C, D) Semi-quantitative analysis of PI3K and p-Akt. This analysis confirmed the significant increase of these molecules in the SD+DSS group compared with ED+PB+DSS-treated mice.  $P < 0.05$  \* versus SD (\*) and SD+DSS (<sup>§</sup>). DSS, dextran sodium sulfates; ED, enriched diet; p-Akt, phosphorylated protein kinase; PB, probiotic; PI3K, phosphatidylinositol 3-kinase; SD, standard diet.

**Fig. 7.** (A) (B) Immunohistochemistry of  $\alpha$ -SMA and collagens I–III. Original magnification:  $10\times$ ; scale bar:  $100\ \mu\text{m}$ . The immunopositivity of  $\alpha$ -SMA and collagens I–III was significantly reduced in ED+PB+DSS mice compared with the other DSS-tested groups. (C) (D) Semiquantitative analysis of  $\alpha$ -SMA and collagen I–III. This analysis highlighted the significant decrease in the expression of these molecules in ED+PB+DSS-treated mice compared with the other fibrotic groups.  $P < 0.05$  \* versus SD; \$ versus SD+DSS.  $\alpha$ -SMA, alpha smooth muscle actin; DSS, dextran sodium sulfates; ED, enriched diet; PB, probiotic; SD, standard diet.

large bowel inflammation and fibrosis compared with the mice in other groups.

Histological analyses revealed that inflammatory infiltrates and the signs of fibrosis were significantly ameliorated in mice receiving ED+PB+DSS. In this group, we detected a decreased expression of the inflammatory molecules IL-1 $\beta$ , IL-6, and TNF- $\alpha$  compared with the SD+DSS, ED+DSS, and SD+PB+DSS groups, as supported by semiquantitative evaluation.

Immunohistochemical and semiquantitative analyses for TGF- $\beta$ 1, p-SMAD3, PI3K, p-Akt,  $\alpha$ -SMA, and collagens I–III showed a decreased expression of these inflammatory and fibrotic markers in the ED+PB+DSS group. These data show the efficacy of the olive compounds and the probiotic to modulate the profibrotic signaling induced by both the TGF- $\beta$  canonical and noncanonical pathways.

These results show that the oral administration of a diet enriched in fermented olive cream and *Lpb. plantarum* IMC513 exerted a beneficial role toward the prevention and development of chronic inflammation, but only when they had been concomitantly administered (Fig. 8). These results can be explained in part by the fact that the olive cream used in this study preserved most of the compounds present in the olive and a retained high concentration of their hydrolyzed hydrophilic derivatives, which are partially lost during the separation of extra virgin olive oil.

Some olive cream components may be the preferred fermentation substrates for *Lpb. Plantarum* strains, leading to the production of beneficial metabolites for the gut mucosa, such as short chain fatty acids [90]. Of the short chain fatty acids, butyrate represents the main energy substrate of colonocytes and is an important factor in the regulation of the local intestinal immune response [91]. Furthermore, the reduced production of butyrate is also involved in colorectal carcinogenesis [92]. *Lpb. plantarum* strains interacting with specific components of olive cream may acquire protective properties for the intestinal mucosa. This study's data represent a good starting point to improve understanding of the relationship

between diet habits and intestinal flora composition in order to identify new approaches for the prevention and/or treatment of chronic intestinal inflammation such as IBD and its related intestinal fibrosis and cancer. Although the exact etiology of IBD is still unknown, diet is one of the major environmental factors involved in its pathogenesis [93–95] as well in the pathogenesis of other intestinal disorders such as microscopic colitis and irritable bowel syndrome [96,97]. Some components of the diet act, on one hand, by modifying the diversity of the microbiota gut, and on the other, by acting directly on the metabolism of the intestinal mucosa, with both processes being responsible for maintaining the intestinal barrier function. The synergistic action of the phenols of olive cream with *Lpb. plantarum* could act in the maintenance or even in the strengthening of the mucosal barrier functions and therefore could have benefits not only for IBD and irritable bowel syndrome but also for microscopic colitis. Furthermore, the antifibrotic action on the intestine shown by the association of the olive phenols with *Lpb. plantarum* could play a favorable role in preventing or slowing down the fibrogenesis process that occurs in IBD. Potentially, the phenols of the olive cream could be used in IBD, microscopic colitis, and irritable bowel syndrome directly as a dietary supplement or as a food fortification with these compounds.

## Conclusions

This study's preliminary results prompted us to hypothesize that olive cream with its potential prebiotic effects and the *Lpb. plantarum* IMC513 strain could restore the gut-microbiome ecosystem. It is widely accepted that in general, both prebiotics and probiotics may improve the gut dysbiosis in chronic colitis [94–96]. Further studies are needed to define the cellular and molecular mechanisms that are modulated by olive cream compounds and by *Lpb. plantarum* IMC513.

**Fig. 8.** The effect of a diet enriched with fermented olive cream enriched and probiotic administration on DSS-induced colitis. (A) After a DSS injury, inflammatory cytokines are released. A persistent inflammation status leads to myofibroblast activation and consequently to an abnormal deposition of extracellular matrix proteins. These events result in the onset of a fibrotic process. (B) The simultaneous consumption of a diet enriched with fermented olive cream enriched and *Lactiplantibacillus plantarum* IMC513 was able to reduce intestinal inflammation (by reducing IL-6, IL-1 $\beta$ , TNF- $\alpha$ , and PI3K signaling) and the development of fibrosis (by decreasing the expression of TGF- $\beta$ , p-SMAD3, PI3K, p-Akt,  $\alpha$ -SMA, and collagens I–III).  $\alpha$ -SMA, alpha smooth muscle actin; DSS, dextran sodium sulfates; IL, interleukin; p-Akt, phosphorylated protein kinase; PI3K, phosphatidylinositol 3-kinase; SMAD, small mothers against decapentaplegic protein; TGF, transforming growth factor; TNF, tumor necrosis factor.

## Acknowledgments

The authors gratefully acknowledge Synbiotec S.r.l. (Camerino, Italy), which kindly provided us with *Lpb. plantarum* IMC513.
